(54) Title: **SWEPT RANGE GATE RADAR SYSTEM FOR DETECTION OF NEARBY OBJECTS**

(57) Abstract

A cost-effective ultrawide band radar system (32) capable of locating nearby buried objects such as reinforcing steel rods, pipes and other objects buried in concrete, soil, behind walls or in the air. A sequence of ultrawide band radar pulses are emitted without a carrier and the system (32) detects reflected pulse energy caused by the transmitted pulse whenever encountering a change in the medium, i.e. an air to metal change or concrete to metal change. This reflected energy is detected and visually displayed. A range gate delay is continuously varied, thus changing the distance from the unit to where the reflected energy would be potentially detected from the target. By continuously sweeping the "depth" of the scan, the operator need only move the unit in two dimensions across the surface to detect objects buried or hidden at varying depths interior to or behind the surface.

SWEPT RANGE GATE RADAR SYSTEM FOR DETECTION
OF NEARBY OBJECTS

5

BACKGROUND OF THE INVENTION

Field of the Invention

10 This invention relates to radar systems, and more specifically to a short range and inexpensive radar system for use in locating reinforcing steel rods, pipes, and other nearby objects buried in concrete, soil, or behind walls and other applications.

DESCRIPTION OF THE PRIOR ART

15 A requirement exists for a cost-effective system capable of locating reinforcing steel rods (rebar), pipes, and other objects buried in concrete, soil, behind walls, etc. Various devices and systems currently exist to locate these various objects, but 20 all are either limited in capability or very costly.

25 Zircon Corporation, Campbell, California, currently produces an electronic stud sensor for locating wooden and metal wall studs behind sheetrock and can sense studs up to 1" to 1½" deep beneath other material such as sheetrock, plywood, etc.

30 Lawrence Livermore National Laboratory (LLNL) has developed an ultra-wide band (UWB) radar technology applicable to produce a stud-sensing type of apparatus. See U.S. Patent application serial no. 08/058,398 35 entitled "Impulse Radar Stud Finder", filed May 7, 1993, invented by Thomas Edward McEwan, incorporated by reference.

35 See also U.S. Patent Applications serial no. 08/044,717 entitled "Ultra-Wideband Motion Sensor," filed Sept. 3, 1992; and serial no. 08/044,754 entitled "A Differential Receiver for Ultra-Wideband Signals

5 filed Sept. 1, 1992, both invented by Thomas Edward
McEwan and also incorporated by reference. Unlike the
zircon product which relies upon sensing a change in
density via capacitive loading, the above-described
10 LLNL technology as shown in present Figure 1 emits a
sequence of ultra-wide band radar pulses without a
carrier and detects deflected pulse energy caused by
the transmitted pulse waveform encountering a change
in medium, i.e., air-to-metal or concrete-to-metal,
15 hereafter referred to as the target. This reflected
energy is detected and visually displayed.

20 The LLNL technology generates a fast pulse
(typically 100 to 1000 ps wide) from a 1 MHz oscillator
25 driving a step generator 12 which is coupled to a
transmit antenna 14. A separate receive antenna 16 is
coupled to a sampler circuit 18 which is gated on with
a delayed version of the transmit pulse by a fixed
range delay generator 22 driving a second step
generator 20. The receiver (including sampler circuit
30 18 feeding amplifier and background subtract circuit 24
coupled to display 26) thus "looks" for reflected
energy at a fixed time delay after the transmit pulse
has occurred. This generates a so-called "range gate",
which is well known in the radar field.

35 This fixed range gate allows detection of objects
at a fixed physical distance from the unit as dictated
by a) the unit's range gate delay, b) the material(s)
the pulse energy is passing through and c) the speed of
light.

40 In a fairly fixed and repeatable situation such as
sensing wall studs behind sheetrock, the range gate
delay time can be fixed at a standard distance because
little variation occurs in home and other building
construction techniques. However, if a broad variety
45 of sensing applications is required such as those
described above, then it has been found that a fixed

range gate delay unit will not suffice. The operator could have a manually variable range gate control, but this would require: a) physical scanning with the unit in both vertical and horizontal planes across a 5 surface, b) changing the range gate control at each point desired to scan and c) doing a new background subtract (recalibration) at each of these range gate settings. This would be a very tedious and error-prone type of operation.

10

SUMMARY OF THE INVENTION

The present invention improves upon the prior art fixed range gate delay approach for UWB radar by continuously varying the range gate delay, thus 15 changing the distance from the unit to where reflected energy would be potentially detected from a target. By continuously sweeping the "depth" of the scan, the operator need only move the unit in two dimensions across a surface to detect objects buried or hidden at 20 varying depths interior to or behind the surface, or otherwise spaced apart from the unit.

Several technical problems have been both discovered and solved by the present inventor to accomplish this. First, at any given range gate delay, 25 it has been found that a certain amount of random, reflected energy will be returned to the receive antenna. This "clutter" is due primarily to finite transmit and receive antenna structure and circuit isolation. To accommodate a cost-effect solution 30 without resorting to much more costly microwave techniques, a certain amount of this clutter is tolerated. The "background subtract" circuit in prior art Figure 1 does a single one-time subtraction at calibration and removes or subtracts these residual, 35 unwanted return signals which, for a single, fixed range gate delay, will be fairly constant for any given

physical orientation such as scanning a sheetrock wall.

If, however, the range gate is continuously varied, it has been found that the "background clutter" also continuously varies in a random fashion in

5 synchronicity with the range gate sweep. To overcome this, in accordance with the invention the range gate is stepped in small increments and at each step, a unique background removal value is sensed and stored in an initial calibration routine. Once accomplished in
10 any physical sensing situation, such as scanning a concrete wall, the stored background values are then subsequently recalled at each range gate step and subtracted from whatever the actual return signal is at that particular range setting, thus leaving for display
15 processing only the change in reflected energy from a "calibrated" situation, such as the detection of embedded rebar in the concrete.

A second problem found with sweeping the range gate is that the reflected energy from a "target" decreases (assuming constant pulse transmit energy) as the square of the distance, as is well known for radio wave propagation. Therefore, a gain that varies proportionally to the square of the range gate delay is incorporated to remove the varying detection distance
25 from the amplitude of the reflected energy. This is important in that the amount of reflected energy has significance as indicating the size and material of the reflecting target.

Thirdly, it has been found that it is desirable
30 that the range gate delay vary in direct linear proportion to the range gate sweep control. This allows a direct calibration "depth" indication of the target from the unit. A correction factor has also been determined to be required to obtain a calibrated
35 depth readout. The dielectric constant (ϵ_R) of the bulk material through which the pulse is passing affects the

velocity of propagation by the square root of ϵ_R . Thus, to obtain the actual depth or distance from the sensing unit's antennas to the reflecting target, a process using the following calculation is used:

5 $D = (.5)(t_D)(C)(\epsilon_R)^{-1/2}$

where D = distance from antenna(s) to the target,

t_D = total round trip delay time of pulse,

ϵ_R = bulk dielectric constant of medium, and

c = speed of light

10 The factor of .5 is required due to the pulse being a "round trip" from the transmit antenna to the target and back to the receive antenna.

15 To summarize, a swept range gate system in accordance with the invention may include at least these structures and corresponding methods beyond that required for a prior art fixed range gate unit: linear range gate time; corrected gain with distance; and multi-point background subtraction.

20 In addition, dielectric constant correction is provided for a calibrated distance display.

While the UWB system disclosed herein operates over a range of 2 MHz to 10 to 15 GHz, having harmonics at each multiple of 2 MHz, this is not limiting.

25 BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 shows a prior art fixed range gate radar system.

30 Figure 2 shows a block diagram of a swept range gate ultra wideband radar system in accordance with the present invention.

Figure 3 shows waveforms illustrating the swept range gate system timing of the system of Figure 2.

Figure 4 shows a diagram of a display as used in accordance with the system of Figure 2.

35 Figure 5A, 5B and 5C show examples of a display

corresponding to particular detection situations in accordance with the present invention.

Figure 6 shows a voltage controlled delay generator in accordance with the present invention.

5 Figure 7 shows an antenna structure in accordance with the present invention.

Figure 8 shows a transmitter in accordance with the present invention.

10 Figure 9 shows a receiver in accordance with the present invention.

DETAILED DESCRIPTION OF THE INVENTION

The various features in accordance with the invention as described above may be accomplished by a combination of analog and/or digital circuitry and/or software executed e.g. in a microprocessor. Figure 2 shows one embodiment of a system 32 that includes these features.

20 A 2 MHz master oscillator 36 drives two paths: a first path via a voltage controlled variable delay circuit 38 and then to the transmit pulse generator 40, and a second path through a fixed delay circuit 42 and then to the receive pulse generator 44. The fixed delay circuit 42 is similar to variable delay circuit 38, without the variable elements (see below, Figure 6).

25 The voltage controlled variable delay 38 allows changing the time of the transmit pulse with respect to the receive pulse generator 44, with a digital-to-analog converter (D/A) 50 providing a varying voltage under control of a conventional microcontroller 52. This structure then generates a continuously changing time delay from some minimum to maximum delay time, creating the swept range. A typical sweep frequency is 35 100 Hz.

The fixed delay in the receiver path is set equal to or greater than the maximum transmit delay. The timing relationship of the transmit pulse generator 40 and receive pulse generator 44 then determines the 5 distance range over which the unit will scan.

Figure 3 depicts this timing by waveforms showing the output signals of various portions of the unit 32. The configuration of Figures 2 and 3 is thus opposite that conventionally used in radar systems where the 10 transmit pulse time is fixed and the receiver gate time is varied. (The conventional configuration may be utilized for the present invention but is not the preferred embodiment.) Sweeping the receive delay conventionally has been found to create additional 15 background clutter due to extraneous signal coupling in the presence of high gain amplifiers and "droop" on the sampler hold capacitor 56, undesirably creating a phase-modulated replica of the range sweep control voltage. These disadvantages are eliminated when the 20 transmit pulse is varied instead.

With reference to Figure 3, times t_{D1} and t_{D2} are the minimum and maximum respectively of the transmit voltage-controlled pulse delay 38. The receive pulse delay 42 is fixed at t_{D3} . Thus, the minimum range is 25 set by $t_{D3} - t_{D2} = t_{D4}$ (which could be equal to zero). The maximum range is $t_{D3} - t_{D1}$. The transmit delay can be any value between these limits as defined by the microcontroller 52 via the D/A 50 driving the voltage variable delay circuit 38.

30 In operation, when the delay between the transmit 40 and receive pulse generator 44 is equal to the round trip transit time of the transmit pulse reflecting off a target, the receive sampler 54 will be turned on coincident with the arrival of the return echo and the 35 sampled and held signal is amplified by amplifier 58.

Prior to any actual sensing, a calibration process

is performed to remove the background "clutter". At each finite range gate control voltage from D/A 50, with the gain of voltage variable gain circuit 62 set via D/A 64 to a previously determined setting, offset 5 D/A 66 driving the offset voltage control of amplifier 58 is varied with a successive approximation routine (or other search routine resident in microprocessor 52) until the output of A/D 70 is at mid-range. The offset binary number (value) driving offset D/A 66 is then 10 stored in microcontroller 52 memory and the range gate D/A 50 is stepped to the next value along with the appropriate gain control D/A 64 binary number (value). The offset D/A 66 search routine is repeated and the number saved. This process is repeated until all range 15 gate control settings have been processed in this manner. (It is to be understood that writing a software routine carrying this out via microprocessor/ microcontroller 52 is well within the ability of one of ordinary skill in the art.) The variable gain circuit 20 62 is any circuit for varying a gain by a voltage control. The unit 32 must be physically stable with relationship to a surface or pointed into the surface as this routine is performed. (This calibration process is applicable, with appropriate readily 25 apparent modifications, to an UWB radar system where the receiver is range swept rather than the transmitter.)

After initial calibration, normal operation can commence. At each range gate D/A 50 setting, the 30 offset D/A 66 and gain D/A 64 settings associated with this range are recalled by the microcontroller 52. With no echo at any range settling, the output of A/D (analog to digital converter) 70 will always be at mid-scale, as any previous background is subtracted out by 35 the offset D/A 66. If, however, an echo is present representing a target at some given distance and range

gate setting, the A/D 70 output will not be mid-scale but some other value. This difference from mid-scale is then processed by the microcontroller 52 and displayed on graphics display 74.

5

Display

The described system provides a number from the A/D 70 related to the strength of the return echo which is uniquely associated with a given range value. The 10 display 74 (e.g., an LCD or other conventional display) therefore, has two pieces of information to visually display: amplitude and range. All physical movement of the unit 32 over the surface being scanned is done by the operator, with any given display presentation being 15 uniquely associated with a given position of the unit on the surface. Thus the operator has physical control of the X and Y coordinates (i.e. the surface being scanned) and the unit 32 scans electronically via the range gate the Z axis (i.e. into, behind, etc., the 20 surface being scanned). ("Surface" need not be a structure per se but could be merely the surface of unit 32 where it is in contact with the air.) Any change in amplitude on the display can now be 25 associated with a unique point within the volume of the object being scanned (X, Y & Z) with amplitude giving an indication of size and material, of objects buried/hidden interior to the volume.

Since the operator is physically doing all X and Y axis scanning, the display 74 should not reflect any 30 bias to either X or Y movement to prevent any operator confusion or misinterpretation. Figure 4 depicts a planar graphics display as an example of display 74 of Figure 2 and that has two axis of information: range 35 (Min to Max) and amplitude (zero to Max on either side of the centerline). The display 74, as physically attached to the unit, is orthogonal to the surface

being scanned when the unit 32 is in use. The display 74 thus provides a representation of the cross-section of the volume being scanned at that physical location on the surface. The display of amplitude information 5 is in one embodiment "mirror imaged" about the center line shown to eliminate any X-Y bias. Figures 5A, 5B, 5C show several display examples.

Figure 5A shows the display 74 of unit 32 when the volume being scanned contains only homogeneous material 10 within the scan range of the unit.

Figure 5B shows the detection of metal rebar at depth D1 into the volume and depicted on the display at position D1' indicating the depth.

Figure 5C is similar to Figure 5B but with the 15 rebar at a greater depth D2, shown on display 74 at position D2'.

The number of range gate values scanned, the 20 amplitude A/D 70 resolution, number of display 74 pixels, range depth and other system parameters can be varied to suit the intended application.

Range Gate Linearity

As previously mentioned, to obtain a calibrated range display, the range gate (or voltage variable 25 delay) must correlate to a given binary number sent to the variable delay D/A 50. If the voltage-to-delay function of the voltage controlled delay 38 were linear, the D/A 50 output need only be scaled to obtain the required range. However, due to the very small 30 delays required (typically less than 10 ns maximum which equates to 5 feet round trip in air) a convenient method (see Figure 6) to obtain voltage controlled delay uses fast logic elements 80, 82 (gates such as buffers, inverters, etc. of logic families such as HC 35 and AC) and slightly varies the delay between gates 80, 82 with R-C (resistor-capacitor) delays as shown.

Resistor R1 and capacitor C1 delay the output of the first gate 80. Varying the control voltage on resistor R2 can slightly modify this delay. The voltage-to-delay transfer function is not linear, however.

5 If the control voltage 50 were alternatively to be driven by a linear sawtooth analog voltage such as from an analog sawtooth generator, means must be provided (not shown) to linearize the time/voltage transfer function.

10 However, in the system block diagram shown in Figure 2, the binary word (value) sent to the delay control D/A 50 can be modified to other than a linear binary sequence to correct for any nonlinearities in the circuit of Figure 6. This linearity correction is
15 part of the microcontroller 50 resident software and once determined for a given design of unit 32 for particular type of logic elements, parts values, etc., would be identical in all other units.

20 Dielectric Constant Correction

As stated above, the dielectric constant of bulk material being scanned affects the pulse propagation time, and thus is taken into account in accordance with the invention at reference number 86 of Figure 2 to
25 realize a calibrated "depth" display.

The dielectric constant of various materials is well known and any conventional input device 86 to the microcontroller 52 such as rotary switches, a keypad, etc. (not shown) may be utilized to select the
30 appropriate constant that the microcontroller 52 could then use in the distance (depth) determination described above. A range of ϵ_r from 1 (air) to 80 (water) would cover most potential applications. A printed table of various materials and their ϵ_r 's is
35 then attached to the exterior of unit 32, as well as possibly having user controlled switch positions to

select a variety of often used applications such as concrete, $\frac{1}{2}$ " sheetrock, tile roof, etc. This would simplify the user's operation of unit 32.

5 Antennas

The prior art device of Figure 1 uses monopole antennas above a ground plane with no cavities or electro-magnetic field isolation from each other.

10 It has been found by the present inventor that it is desirable to isolate the transmit and receive antennas as much as possible consistent with other requirements (such as cost and size) so that the receiver need not cope with the very large transmitted pulse, as compared to the much weaker return echo.

15 Also, to obtain the most unambiguous range determination, the transmit pulse is a single pulse with little or no ringing.

It has been found that broadband antenna structures accomplish this. Figure 7 shows the antenna structure of one embodiment of the present invention. Both the transmit monopole 88 and receive monopole 90 are in separate, rectangular cavities respectively 92, 94 in a metal enclosure 98, which cavities provide isolation and semi-broad bandwidth.

25 Termination resistors R1, R2 and R3, (not the same as similarly labelled components in Figure 6) are selected to minimize any ringing. The dimensions 11, 12, 13 are respectively 2.0", 1.5", and 1.0". The lengths 14, 15 of respectively monopoles 88, 90 (see 30 Figures 8 and 9) are respectively 1.2" and 1.2".

Figure 8 shows the transmitter pulse generator 40 and the transmitter monopole 88 and termination components R1, R2 and C3 of Figure 7. The pulse generator 40 includes transistor Q1 having a value of f_T (unit gain cutoff) greater than or equal to 7 GHz. The 35 base of transistor Q1 is connected as shown via a

capacitor to the variable delay generator 38 of Figure 2.

Figure 9 shows in addition to the receiver sampler 54 and the associated pulse generator 44, which 5 includes pulse generator transistor Q2 as driven by the fixed delay circuit 42, the receive monopole 90 with its termination transistor R3 as in Figure 7.

Transistor Q1 is similar to transistor Q2. The sampler 10 54 includes two Schottky diodes D1 and D2. One terminal of the hold capacitor 56 is connected to the amplifier 58 of Figure 2. It is to be understood that the values for the component shown in Figures 8 and 9 are exemplary and not limiting.

Monopole antennas, as used herein, are linearly 15 polarized, so that when attempting to detect rod-like objects such as rebar, the axis of the antennas 88, 90 needs to be parallel with the length of the rebar for maximum detection. If the unit 32 were rotated 90 degrees such that the axis of the antennas 88, 90 were 20 perpendicular to the length of the rebar, the signal return would be minimal. This property could be useful in determining the rebar orientation within a medium (i.e. concrete), but requires the operator to be aware of this parameter and search in multiple rotated axis.

If circularly polarized antennas as known in the 25 art were utilized (not shown), both for the receiver and transmitter, the orientation of a rod type target would not matter, as the circular polarization of the waves would not differentiate between various rod 30 rotation positions.

Another antenna embodiment (also not shown) uses circularly polarized antennas which allow various target configurations to be at any orientation without comprising the return echo strength.

35 If the target is a material surface (such as sheet metal) of a size equal to or larger than the antenna

5 cavities' frontal area, antenna circular polarization (CP) yields no benefits and in fact produces a loss of 3dB per antenna as CP type antenna structures are well known to produce. Therefore, the choice of antenna for
a given sensing situation should take into account the physical configuration of the intended target, and hence various antennas are applicable in accordance with the invention.

10 A system and method in accordance with the present invention is not limited to the particular applications described above, but has other applications for sensing of objects, not limited to the construction type field. For instance the system is applicable to sensing objects located in air that are relatively near the
15 unit for purposes of security systems, traffic control situations (e.g. for installation in automobile to detect proximity to another automobile or other object), and for other applications requiring detection of objects at a relatively short distance (within 200
20 feet) where a low cost system is important. This disclosure is illustrative and not limiting. Further modifications will be apparent to one of ordinary skill in the art, and are intended to fall within the scope of the appended claims.

CLAIMS

1. A range swept ultra wideband radar system adapted for sensing a nearby target comprising:
 - 5 a signal transmitter driven by a continuously variable delay circuit; and
 - a receiver located for receiving the signals transmitted by the transmitter after being reflected from the nearby target;
 - 10 wherein the variable delay circuit includes a source of a variable voltage for determining an amount of the delay.
2. The system of Claim 1, wherein the receiver is driven by a fixed delay.
- 15 3. The system of Claim 1, wherein the transmitter transmits at a range of frequencies between 2 MHz and about 10 GHz, having harmonics at fixed intervals in the range.
- 20 4. The system of Claim 1, further comprising:
 - means for stepping the variable delay in predetermined increments;
 - means for determining at each increment a received amount of a background signal;
 - 25 means for storing the determined amount of the background signal for each increment; and
 - means for subsequently correcting a received signal at a particular variable delay by the stored amount.
- 30 5. The system of Claim 1, further comprising a first antenna element connected to the receiver, the first antenna element being a monopole located in a first rectangular cavity having conductive walls.

6. The system of Claim 5, further comprising a second antenna element connected to the transmitter, the second antenna element being a monopole located in a second rectangular cavity having conductive walls.

5

7. The system of Claim 1, further comprising a circularly polarized antenna element connected to the transmitter.

10

8. The system of Claim 1, further comprising a circularly polarized antenna element connected to the receiver.

15

9. The system of Claim 1, further comprising a conductive enclosure defining two rectangular cavities, a monopole being mounted in each cavity, one of the monopoles being connected to each of the receiver and transmitter.

20

10. The system of Claim 1, further comprising a display operatively connected to the receiver, the display showing in a first dimension a distance of the target from the system and in a second dimension an amplitude of the received signal.

25

11. The system of Claim 10, the display further displaying an image of the distance and amplitude symmetrical about a center line of the display.

30

12. The system of Claim 1, further comprising: means for indicating a particular dielectric constant of an environment of the target; and means for determining a distance of the target from the unit using the indicated dielectric constant.

35

13. The system of Claim 1, further comprising:
means for determining a correction value for
a gain related to a square of the variable delay
at any particular distance; and
5 means for applying the correction value to
the gain applied to the received signal.

14. The system of Claim 1, the variable delay
circuit including:

10 a first logic gate having an output terminal
connected to an input terminal of a second logic
gate;
a variable voltage being connected to the
input terminal of the second logic gate.

15 15. A range swept ultra-wideband radar system
adapted for sensing a nearby target, comprising:
a transmitter emitting radio signals at a
plurality of frequencies in a range of about 2 MHz
20 to about 10 GHz, the plurality of frequencies
being spaced apart at a constant frequency
interval; and
a receiver located for receiving the emitted
signals after being reflected from the target,
25 wherein the receiver is driven by a variable delay
thereby determining a distance of the target from
the system.

16. A range swept ultra-wideband radar system
30 adapted for sensing a nearby target, comprising:
a signal transmitter;
a receiver located for receiving the signals
emitted by the transmitter after being reflected
from the target;
35 a variable delay for sweeping a selected one
of the emitted and received signals;

means for stepping the variable d in predetermined increments;

means for determining at each increment a received amount of a background signal;

5 means for storing the determined amount of the background signal for each increment; and

means for subsequently correcting a received signal at a particular variable delay by the stored amount.

AMENDED CLAIMS

[received by the International Bureau on 22 January 1996(22.01.96); original claim 2 cancelled; original claims 1, 4-6, 9, 12, 13, 15 and 16 amended; new claims 17-27 added; remaining claims unchanged (7 pages)]

1. A transmitter range swept ultra-wideband radar system adapted for sensing a nearby target comprising:
 - 5 a signal transmitter driven by a continuously variable time delay circuit; and
 - a receiver driven by a fixed time delay circuit and located for receiving the signals transmitted by the transmitter after being reflected from the nearby target;
- 10 wherein a pulse time of the transmitter is variable and a gate time of the receiver is fixed.
- 15 3. The system of Claim 1, wherein the transmitter transmits at a range of frequencies between 2 MHz and about 10 GHz, having harmonics at fixed intervals in the range.
- 20 4. The system of Claim 1, further comprising:
 - means for stepping the variable delay in predetermined increments;
 - means for determining at each increment a received amount of a background signal which is clutter and not reflected from the target;
 - 25 means for storing the determined amount of the background signal for each increment; and
 - means for subsequently correcting a received signal at a particular variable delay by the stored amount.
- 30 5. The system of Claim 1, further comprising a first antenna element connected to the receiver, the first antenna element being a first monopole which is resistively loaded and located in a first rectangular cavity having conductive walls.
- 35 6. The system of Claim 5, further comprising a second antenna element connected to the transmitter, the second antenna element being a second monopole which is

resistively loaded and located in a second rectangular cavity having conductive walls.

7. The system of Claim 1, further comprising a
5 circularly polarized antenna element connected to the transmitter.

8. The system of Claim 1, further comprising a
10 circularly polarized antenna element connected to the receiver.

9. The system of Claim 1, further comprising a
conductuve enclosure defining two rectangular cavities
each having conductive walls, a resistively loaded
15 monopole being mounted in each cavity, one of the
monopoles being connected to each of the receiver and
transmitter.

10. The system of Claim 1, further comprising a
20 display operatively connected to the receiver, the
display showing in a first dimension a distance of the
target from the system and in a second dimension an
amplitude of the received signal.

25 11. The system of Claim 10, the display further
displaying an image of the distance and amplitude
symmetrical about a center line of the display.

12. The system of Claim 1, further comprising:
30 means for indicating a particular dielectric
constant of an environment of the target; and
means for determining a distance of the target
from the system using the indicated dielectric
constant.

35

13. The system of Claim 1, further comprising:
means for determining a gain correction value
related to any particular distance to the target;
means for applying the correction value to a
5 gain applied to the received signal; and
means for displaying the received signal with
the corrected gain, thereby to indicate a size and
material of the target.

10 14. The system of Claim 1, the variable delay
circuit including:

a first logic gate having an output terminal
connected to an input terminal of a second logic
gate;

15 a variable voltage being connected to the input
terminal of the second logic gate.

15. A range swept ultra-wideband radar system
adapted for sensing a nearby target, comprising:

20 a transmitter emitting radio pulses at a
plurality of frequencies in a range of about 2 MHz
to about 10 GHz; and

25 a receiver located for receiving the emitted
signals after being reflected from the target,
wherein the receiver is driven by a continuously
variable delay to determine a distance of the target
from the system.

16. A range swept ultra-wideband radar system
30 adapted for sensing a nearby target, comprising:

a signal transmitter;

a receiver located for receiving the signals
emitted by the transmitter after being reflected
from the target;

35 a variable delay for sweeping a selected one of
the emitted and received signals;

means for stepping the variable delay in predetermined increments;

5 means for determining at each increment a received amount of a background signal which is clutter and not reflected from the target;

means for storing the determined amount of the background signal for each increment; and

10 means for subsequently correcting a received signal at a particular variable delay by the stored amount.

17. A range swept ultra-wideband radar system adapted for sensing a nearby target comprising:

15 a signal transmitter driven by a continuously variable delay circuit;

a receiver located for receiving the signals transmitted by the transmitter after being reflected from the nearby target;

20 means for stepping the variable delay in predetermined increments;

means for determining at each increment a received amount of a background signal which is clutter not from the target;

25 means for storing the determined amount of the background signal for each increment; and

means for subsequently correcting a received signal at a particular variable delay by the stored amount.

30 18. A method for detecting an object located behind a surface, comprising the steps of:

applying a radar receiver/transmitter unit to the surface;

35 transmitting a sequence of radar pulses from the radar receiver/transmitter unit into the surface;

receiving the transmitted radar pulses at the unit after the transmitted radar pulses are reflected from the object; and

5 continuously sweeping a range gate delay between the transmission and receipt of the radar pulses;

10 moving the unit in two directions on the surface to a plurality of locations on the surface; and

15 indicating a depth of the object from the surface and a size of the object at each location, from the range gate delay of the radar pulses at that location.

19. The method of Claim 18, wherein the step of continuously sweeping the range gate delay comprises the steps of:

receiving the radar pulses at a fixed time delay; and

20 varying a gate time of the transmission of the radar pulses.

20. The method of Claim 18, wherein the radar pulses are each an ultra-wideband pulse having a plurality of frequencies in a range of at least 2 MHz to 25 10 GHz, and a duration of less than 1000 ps.

21. The method of Claim 18, wherein the step of continuously sweeping includes sweeping from a minimum 30 delay to a maximum delay at a frequency of about 100 Hz.

22. The method of Claim 18, further comprising the steps of:

35 stepping the range gate delay in predetermined increments;

determining at each increment a received amount of a random, reflected energy background signal;

storing the determined amount of the background signal for each increment; and

5 subsequently correcting the received pulses at a particular range gate delay by the stored amount.

23. The method of Claim 18, further comprising the steps of:

10 indicating a particular dielectric constant around the object; and

determining the depth of the object from the surface using the indicated dielectric constant.

15 24. The method of Claim 18, further comprising the steps of:

determining a gain correction value related to any particular depth of the object from the surface;

20 applying the gain correction value to a gain applied to the received pulse; and

wherein the step of indicating uses the corrected gain, thereby to indicate a size and material of the object.

25 25. The radar system of Claim 15, wherein the delay is variable under control of a microcontroller coupled to the receiver.

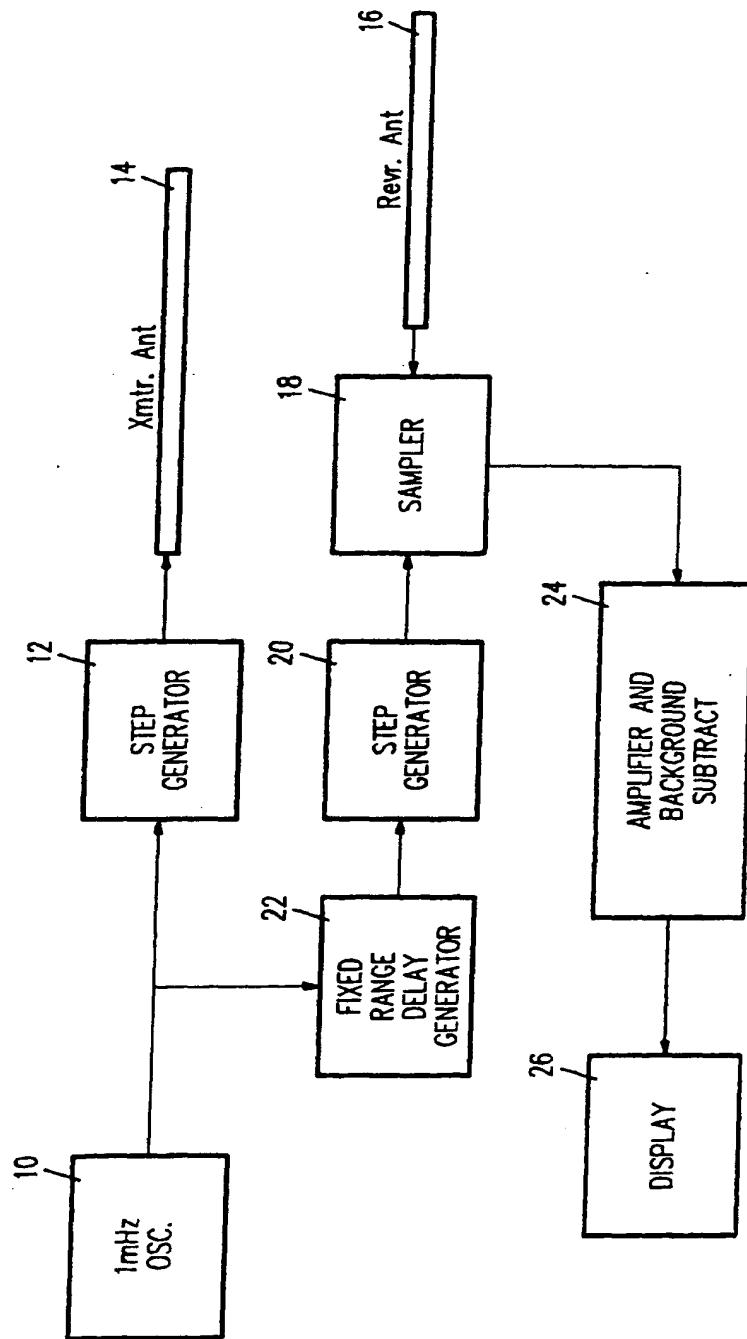

30 26. A range swept ultra-wideband radar system adapted for sensing a nearby target, comprising:

a transmitter emitting ultra-wideband radio pulses, wherein the transmitter is driven by a continuously variable delay to determine a distance of the target from the system; and

35 a receiver located for receiving the emitted signals after being reflected from the target.

27. The radar system of Claim 26, wherein the delay is variable under control of a microcontroller coupled to the transmitter.
